## INTRODUCTION

This paper reports on an investigation of a series of compounds of the NO<sub>y</sub> family, based on high resolution infrared solar observations made at the ISSJ (International Scientific Station of the Jungfrauoch), Switzerland (46.55°N, 7.99°E, 3580 m a.s.l.). These observations are part of a long-term monitoring effort undertaken by the Liège group since the mid-1970s, and integrated more recently as a contribution to the Network for the Detection of Stratospheric Change (NDSC).

Currently, vertical column abundances of over 20 molecules are retrieved from solar spectra recorded under clear sky conditions as regularly as possible, using two high resolution Fourier transform infrared (2 to 15 μm) spectrometers [1].

The columns are retrieved from the spectra by non-linear least squares spectral fitting, using the SFIT 1.09c algorithm; a discussion of the retrieval procedure can be found in [2].

## NO<sub>y</sub> BUDGET

NO<sub>y</sub>, the total reactive nitrogen, is defined as the sum of the following species: NO + NO<sub>2</sub> + NO<sub>3</sub> + 2(N<sub>2</sub>O<sub>5</sub>) + HNO<sub>3</sub> + HO<sub>2</sub>NO<sub>2</sub> + ClONO<sub>2</sub> + BrONO<sub>2</sub>. For the purpose of deriving the NO<sub>y</sub> column trend above the Jungfrauoch, monthly mean columns of those species that can easily be measured from the ground, i.e. NO, NO<sub>2</sub>, HNO<sub>3</sub> and ClONO<sub>2</sub>, have been calculated from the consistent database spanning from 1985 to present. This procedure of computing monthly means avoids giving excessive weight to months with high-density observations. These mean columns are shown as dots in frames A to D of Figure 1; they have been modeled with linear+sinusoidal functions (continuous curves). Trend values, referred to 1990.0, are also indicated with their 1 σ deviations.

The sum of these monthly mean columns, displayed in Figure 1, frame E, represents the most important part of the total NO<sub>y</sub> as derived from the ISSJ data. The missing NO<sub>3</sub>, N<sub>2</sub>O<sub>5</sub>, HO<sub>2</sub>NO<sub>2</sub> and BrONO<sub>2</sub>, not easily observable from the ground, represent less than 5 % of the total NO<sub>y</sub> [3]

As for the individual species, the NO<sub>y</sub> trend has been simulated with a linear+sinusoidal function (continuous curve); the resulting trend of (0.3 ± 0.3) % per year, although barely significant, is consistent with the trend of (0.35 ± 0.04) % per year, found for the NO<sub>y</sub> gas source N<sub>2</sub>O [4] (Figure 2, frame F). The important uncertainty in the NO<sub>y</sub> trend is mainly due to the high variability of the HNO<sub>3</sub> columns, which is predominant during the November to April months (circulation and heterogeneous processes).

Notice that the constituents considered in the present investigation show seasonal variations summarized in the following table:

	NO	NO <sub>2</sub>	HNO <sub>3</sub>	ClONO <sub>2</sub>
Peak-to-peak variation (%)	34	74	28	37
Occurrence of maximum	June-July	June-July	Feb.-March	March
Occurrence of minimum	January	January	August	September

## HNO<sub>3</sub> AND HF COLUMNS CORRELATION.

In Figure 2, we have correlated the HNO<sub>3</sub> columns with those of HF (with the HF trend removed and reported to 1990.0) obtained on same days. Most of the points cluster about an oblique line: the points on the left correspond to typical summer conditions, whereas those to the right, generally correspond to air masses originating from the higher latitudes, enriched in both HF and HNO<sub>3</sub>, as a consequence of the latter's latitudinal distribution.

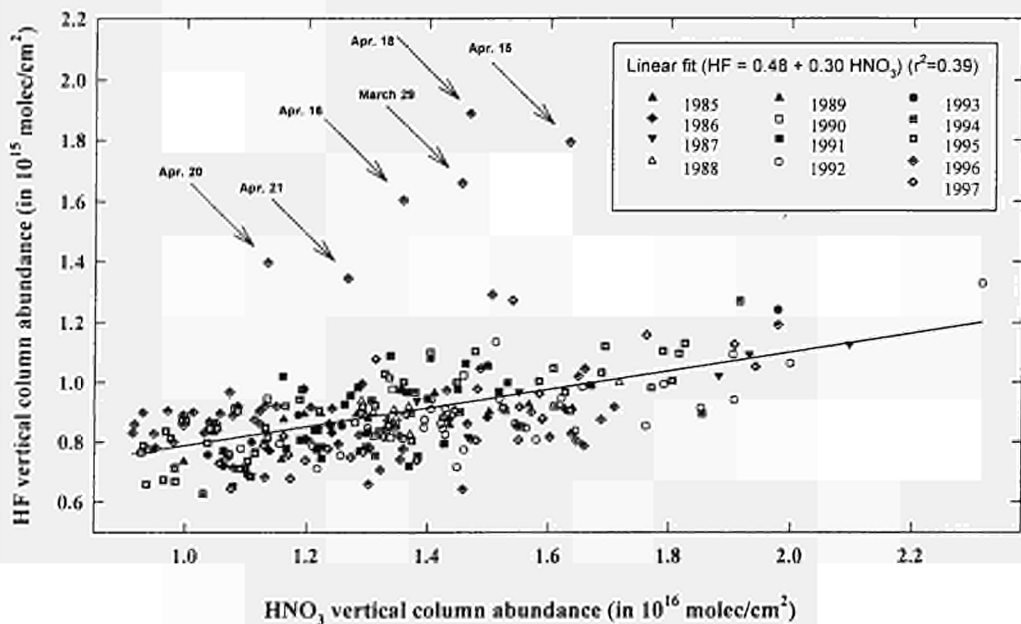

Figure 2: HNO<sub>3</sub> and HF columns correlation

An interesting episode in March - April 1996 is identified in Fig.2 by arrows and dates; during that period, extremely high values of HF (the highest ever recorded above ISSJ) have been observed.

At the end of March, the polar vortex was centered over Scandinavia and was still well defined. Switzerland was near the edge of the vortex (on the 31<sup>st</sup> March, potential vorticity was  $40 \times 10^{-6} \text{ Km}^2 \text{ kg}^{-1} \text{ s}^{-1}$  at the 475 K level). Air masses above the Jungfraujoch originated from the polar regions and were thus enriched in HF; Figure 3 shows an example of back trajectories for the 29<sup>th</sup> March 1996, ending at the closest rawinsonde station (Payerne, 85 km North-West of the Jungfraujoch). The vortex then slowly dissolved: by mid-April, only two fragments remained, one centered over East Siberia, the other over Central Europe. Potential vorticity reached again high values ( $38 \times 10^{-6} \text{ Km}^2 \text{ kg}^{-1} \text{ s}^{-1}$  at the 475 K level on the 18<sup>th</sup> April) above the Jungfraujoch.

During that time period, no specially high values of HNO<sub>3</sub> were observed, as we could have expected from the usual relationship between HF and HNO<sub>3</sub> shown in Figure 2: based on the latter, we should have measure HNO<sub>3</sub> values around  $5 \times 10^{16} \text{ molec./cm}^2$  instead of the values around  $1.5 \times 10^{16} \text{ molec./cm}^2$  actually observed. This suggests that denitrification occurred in these air parcels.

#### ACKNOWLEDGMENTS

Acknowledgment is made for the financial contributions from the Belgian organizations FNRS and OSTC, Brussels. We thank J. Granville, O. Hennen (IASB) and R. Blomme (KSB) who participated in some observational campaigns at ISSJ. We further thank the Stiftungsrat of the Jungfrauoch and the University of Liège for supporting the facilities needed to perform both the observations and their analysis.
