HIGHLIGHTS

- The O₃ decreased in the south but increased in most other regions during lockdowns.
- Meteorological changes and emission reductions both contributed to O₃ changes.
- The O₃ changes in different regions depended on the levels of NO_x and VOC reductions.

GRAPHICAL ABSTRACT

Contribution of meteorological changes and emission reductions to O₃ variations for the daytime during the COVID-19 pandemic

ABSTRACT

Ozone (O₃) is a key oxidant and pollutant in the lower atmosphere. Significant increases in surface O₃ have been reported in many cities during the COVID-19 lockdown. Here we conduct comprehensive observation and modeling analyses of surface O₃ across China for periods before and during the lockdown. We find that daytime O₃ decreased in the subtropical south, in contrast to increases in most other regions. Meteorological changes and emission reductions both contributed to the O₃ changes, with a larger impact from the former especially in central China. The plunge in nitrogen oxide (NO_x) emission contributed to O₃ increases in populated regions, whereas the reduction in volatile organic compounds (VOC) contributed to O₃ decreases across the country. Due to a decreasing level of NO_x saturation from north to south, the emission reduction in NO_x (46%) and VOC (32%) contributed to net O₃ increases in north China; the opposite effects of NO_x decrease (49%) and VOC decrease (24%) balanced out in central China, whereas the comparable decreases (45–55%) in these two precursors contributed to net O₃ declines in south China. Our study highlights the complex dependence of O₃ on its precursors and the importance of meteorology in the short-term O₃ variability.

1. Introduction

The outbreak of coronavirus disease 2019 (COVID-19) has severely threatened public health worldwide, leading to millions of deaths (WHO, 2020). China, where the first case of COVID-19 was reported in the city of Wuhan, imposed country-wide measures from 23 January

to 13 February 2020 to prevent the spread of the disease, including social distancing, teleworking, and closure of non-essential businesses (Chinazzi et al., 2020; Li et al., 2020). These restrictions drastically reduced anthropogenic activities, resulting in a sharp decrease in emissions of air pollutants (Doumbia et al., 2021; Huang et al., 2021; Wang et al., 2020a).

The huge and large-scale emission reductions during the COVID-19 lockdown can be treated as a natural outdoor experiment to improve our understanding of the air pollutant's response to emission control. According to satellite and surface observations, compared with the period before the lockdown, nitrogen dioxide (NO_2) concentrations decreased by over 50% in China during the lockdown period (Bauwens et al., 2020; Liu et al., 2020; Shi and Brasseur, 2020; Zhang et al., 2020). The concentrations of other pollutants, including SO_2 , particulate matter with an aerodynamic diameter less than $2.5 \mu\text{m}$ ($\text{PM}_{2.5}$), particulate matter with an aerodynamic diameter less than $10 \mu\text{m}$ (PM_{10}), and carbon monoxide (CO), also declined in a large area of China (Miyazaki et al., 2020; Wang et al., 2020b). However, surface ozone (O_3) concentrations in northern and central China increased by over 100% (Lian et al., 2020; Shi and Brasseur, 2020). Similar O_3 increases have been reported in southern Europe, India, and Brazil despite the large decrease in other pollutants (Sharma et al., 2020; Sicard et al., 2020; Siciliano et al., 2020). However, the underlying factors driving the O_3 changes during the city lockdowns remain unclear.

Surface O_3 is produced by photochemical reactions of ozone precursors, NO_x , volatile organic compounds (VOCs), and carbon monoxide (CO) and can also be transported from higher levels of the atmosphere and from outside regions (Akimoto et al., 2015; Liu and Wang, 2020a; Roelofs and Lelieveld, 1997). It is well known that O_3 has a non-linear dependence on its precursors and that NO_x can either decrease or increase O_3 depending on the relative abundance of NO_x to VOCs (Atkinson, 2000; Wang et al., 2017a). In general, the O_3 production in urban areas with high NO_x/VOCs ratios is VOCs limited, and reducing NO_x emissions can increase O_3 due to decreased titration of O_3 and radicals. In addition to the two precursors, particulate matters can influence

O_3 by altering the solar irradiance and heterogeneous chemical reactions on aerosol surfaces (Li et al., 2019b; Liu and Wang, 2020b; Stadtler et al., 2018). Meteorological factors affect surface ozone by changing transport pattern, wet and dry depositions, chemical reaction rates, and natural emissions (Liu and Wang, 2020a; Lu et al., 2019).

The responses of ozone (and other air pollutants) to short-term emission reductions have been previously studied for a number of public and political events in China, such as the Beijing Summer Olympic Games (August 2008), the Asia-Pacific Economic Cooperation (APEC) meeting in Beijing (November 2014), and the G20 summit in Hangzhou (September 2016). During these events, various emission-reducing measures were implemented in the cities concerned and their surrounding areas. Whereas atmospheric concentrations of primary air pollutants (NO_x , CO, primary PM, and SO_2) in the concerned cities generally decreased in response to the temporary control measures, the O_3 concentrations showed mixed responses. O_3 decreased after emission reductions for some events (Huang et al., 2017; Wang et al., 2017b) but increased in others (Wang et al., 2010; Wang et al., 2015; Wu et al., 2019). The different O_3 responses have been qualitatively attributed to differences in the meteorological conditions (including regional transport of air masses) and to different control measures implemented by the local governments.

Compared with the previously studied situations, the COVID-19 lockdown is unique in that emissions decreased across the whole country (and later worldwide) as opposed to a specific city or region, and the decreases were also much more drastic than those due to transportation restrictions alone. Moreover, the COVID-19 lockdown took place in winter, whereas the previous interventions occurred in summer and autumn, when meteorology and atmospheric chemistry are different from winter. The present study analyzes surface O_3 data across China before and during the COVID-19 lockdown. We find that O_3 decreased in southern China while increasing in most other regions during the lockdown. Using a regional chemistry transport model, we isolate the impacts of meteorological changes and anthropogenic emission reductions on O_3 . Our results highlight the importance of meteorological

influences on the short-term O₃ changes and the diverse response of O₃ to the emission reductions of its precursors in different climate and emission-mix regions.

2. Materials and methods

2.1. Surface measurement data

We obtained the observed concentrations of surface O₃ and other pollutants (PM_{2.5}, PM₁₀, SO₂, CO, NO₂) at 1643 stations from the China National Environmental Monitoring Center (<http://106.37.208.233:20035/>). Data quality control was conducted for the measurement data in accordance with previous studies (Lu et al., 2018; Song et al., 2017). Fig. 1 shows the locations of these environmental monitoring sites.

The country-wide measures to control the spread of COVID-19 were implemented starting from 23 January 2020 (the exact date varies for

different cities), just before the Chinese New Year. All enterprises remained closed until no earlier than 13 February, except those required for essential public services, epidemic prevention and control, and residential life needs. We focused on the period during the COVID-19 lockdown from 23 January to 12 February 2020 (hereafter referred to as the CLD period), 3 weeks in total. We derived the changes in O₃ and other pollutants by comparing the CLD period with the 3 weeks before the COVID-19 outbreak, from 2 to 22 January 2020 (hereafter referred to as the pre-CLD period). We focused on three typical regions in China (Fig. 1): north China (NC, 35–41.5°N, 113–119°E, including Beijing, Tianjin, Hebei, and western Shandong), central China (CC, 28.8–33°N, 108–117°E, including Hubei province, where Wuhan is situated, and the surrounding regions), and south China (SC, 21.5–24°N, 111–116°E, including the Pearl River Delta and the surrounding regions). The NC region is situated in the North China Plain, which is known to suffer from severe haze in winter; CC was the original epicenter of the COVID-19

(f) The same with (b) but for nighttime average O₃.

outbreak in China and is an important economic hub for the central regions of China; the Pearl River Delta, where the megacities of Guangzhou and Shenzhen are situated, is the most developed region in southern China.

2.2. Numerical modeling

The CMAQ model (Community Multiscale Air Quality model, v5.2.1) was applied to simulate the O₃ mixing ratios over China from 2 January to 12 February 2020. The WRF model (Weather Research and Forecasting model, v3.5.1) was driven by the dataset of the National Center for Environmental Prediction (NCEP) FNL Operational Model Global Tropospheric Analyses with a horizontal resolution of 1° × 1° and

provided meteorological inputs for the CMAQ model. The CMAQ target domain covered the continental China at a horizontal resolution of 36 km × 36 km. SAPRC07TIC (Carter, 2010; Hutzell et al., 2012) and AERO6i (Murphy et al., 2017; Pye et al., 2017) were adopted as the gas-phase chemical mechanism and aerosol mechanism, respectively. The CMAQ model has been improved with updated heterogeneous reactions to better predict the O₃ concentration; details can be found in Liu and Wang (2020a). Although the WRF-CMAQ model was run in offline mode, the CMAQ model employs an in-line method that uses the concentrations of particles and O₃ predicted within a simulation to calculate the solar radiation and photolysis rates (Binkowski et al., 2007). As a result, the effect of aerosol on O₃ concentrations via changing the photolysis rates was also considered

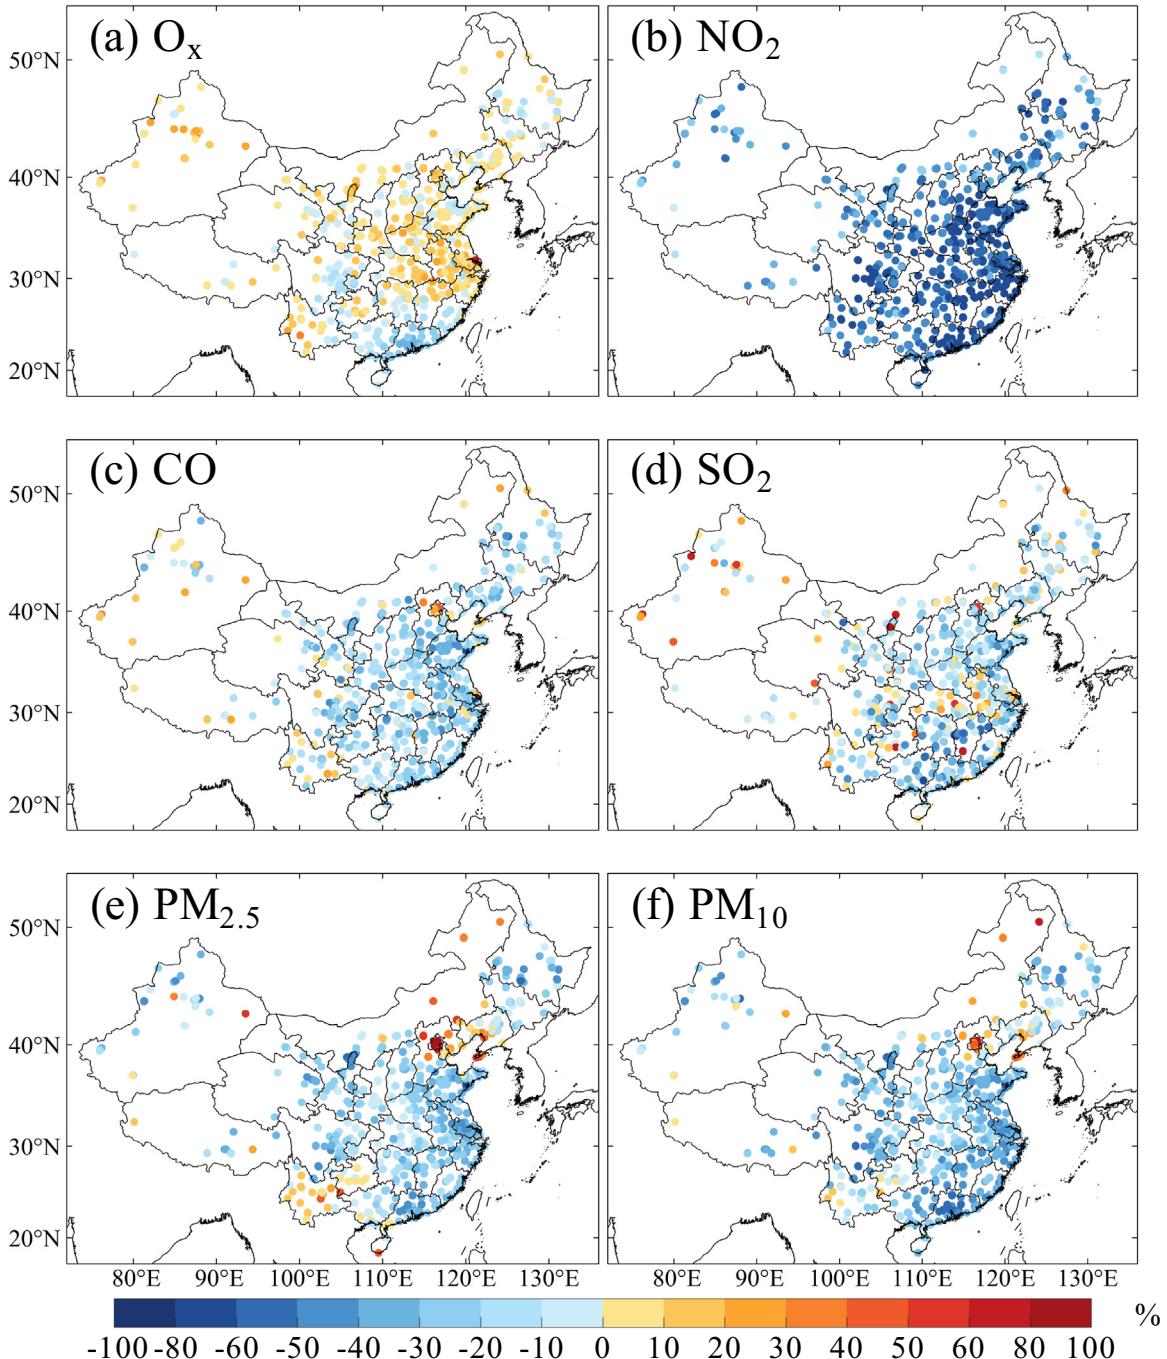

Fig. 3. Percentage change of (a) observed daytime average O_x (NO₂ + O₃), whole-day average (b) NO₂, (c) CO, (d) SO₂, (e) PM_{2.5}, and (f) PM₁₀ concentrations during the CLD period relative to the pre-CLD period.

in the simulation. The chemical boundary conditions were provided by the results of Whole Atmosphere Community Climate Model (WACCM, <https://www.acom.ucar.edu/waccm/download>). The anthropogenic emissions in China were obtained from the Multi-resolution Emission Inventory for China (MEIC) in 2017 (<http://www.meicmodel.org>) with scaling factors to the year 2020 (Table S1, see text in Supplementary Information), which were estimated based on the Three-Year Action Plan (2018–2020) issued by the government and the changes in the multi-pollutant emissions of different sectors in recent years (Zheng et al., 2018). The emission adjustments during the lockdown period are based on recent publications (see text in Supplementary Information). Emissions from the other countries were derived from the MIX emission inventory (Li et al., 2017). International shipping emissions were taken from the Hemispheric Transport Atmospheric Pollution (HTAP) emission version 2.2 dataset for 2010 (Janssens-Maenhout et al., 2015). Biogenic emissions were calculated by the Model of Emissions of Gas and Aerosols from Nature (MEGAN) version 2.1 (Guenther et al., 2012) with meteorological inputs from the WRF model.

Two experiments were conducted to investigate the impacts of meteorological changes and emission reductions on O₃ during the CLD period. The first (baseline) used the same anthropogenic emissions for the pre-CLD and CLD periods, and the second (Reduction case) used emission reductions of 70%, 40% and 30% for transportation, industry and power generation, respectively, and a 10% increase of residential emission during the CLD period. These emission reductions for the whole country were estimated according to the previous literature (Doumbia et al., 2021; Huang et al., 2021; Wang et al., 2020a). Comparing these two model simulations, the O₃ changes during the CLD period relative to the pre-CLD period for the Reduction Case were considered to be entirely due to the meteorological changes and emission reductions. The impacts of the meteorological changes (including the changes in chemical boundary conditions) were quantified by subtracting the O₃ mixing ratios of the pre-CLD period from those of the CLD period for the

baseline experiment, while the impacts of emission reduction were estimated by comparing the O₃ mixing ratio during the CLD period between the Reduction Case and the baseline experiment. Furthermore, we individually reduced the emissions of nitrogen oxide (NO_x), VOCs, CO, PM (particulate matter, including PM₁₀, PM_{2.5}, black carbon, and organic carbon), and SO₂ during the CLD period to elucidate the response of O₃ to each pollutant reduction.

The performance of the CMAQ model in simulating the O₃, NO₂, PM_{2.5}, SO₂, and CO concentrations for the Reduction Case was evaluated (Fig. S1 and Table S2), showing reasonable agreements with the respective surface observations. Details of the emission estimation and the model evaluation are presented in Supplementary Information.

3. Results

3.1. Observed O₃ changes in different parts of China

Figs. 2 and 3 present the changes in observed concentrations of O₃ and other pollutants during the CLD period compared with pre-CLD. The concentrations of most pollutants (SO₂, CO, PM_{2.5}, PM₁₀) that partially or fully originated from the direct emissions declined in China during the lockdown. NO₂, a precursor of O₃, decreased by about 50% across the entire continental China, and by similar amounts in all regions (Fig. 3b). However, the O₃ mixing ratio exhibited varying changes in different regions (Fig. 2a). In NC and CC, the daily average O₃ increased significantly, by 112% and 73%, respectively (Fig. 2b); in contrast, it remained almost unchanged in SC. The O₃ changes also varied between daytime (8:00–20:00 LST) and nighttime (20:00–8:00 LST). During daytime, the O₃ increase in most parts of China was smaller than the daily average (Fig. 2c), 92% and 71% in the NC and CC regions (Fig. 2d). In the SC region, most stations displayed a decrease in O₃ during daytime, leading to a regional average O₃ drop of 14%. During nighttime, the O₃ mixing ratio increased significantly across China (Fig. 2e), by 154%,

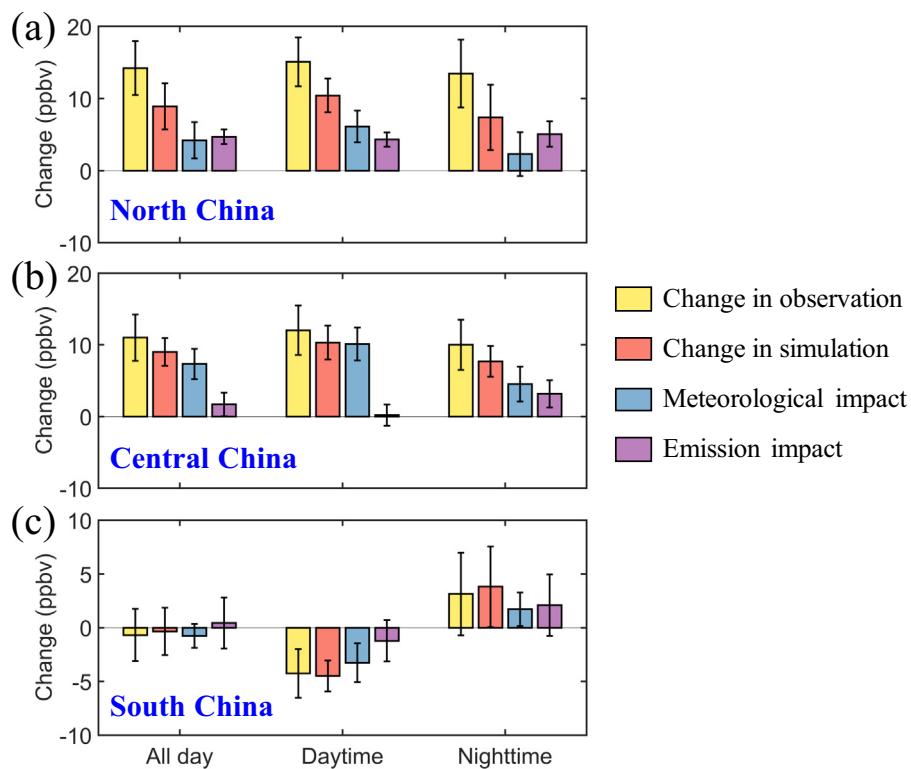

Fig. 4. Changes in O₃ mixing ratios during the COVID-19 lockdown period and contributions from meteorological changes and emission reductions for three typical regions. (a) Observed and simulated changes in O₃ mixing ratios and the contributions from meteorological changes and emission reductions during the CLD period compared with the pre-CLD period in north China (NC). The O₃ changes for the all-day average, daytime average, and nighttime average are presented. (b) The same with (a) but for central China (CC). (c) The same with (a) but for south China (SC). The locations of these three regions are shown in Fig. 1. Note that the error bars mark the standard deviations within the region.

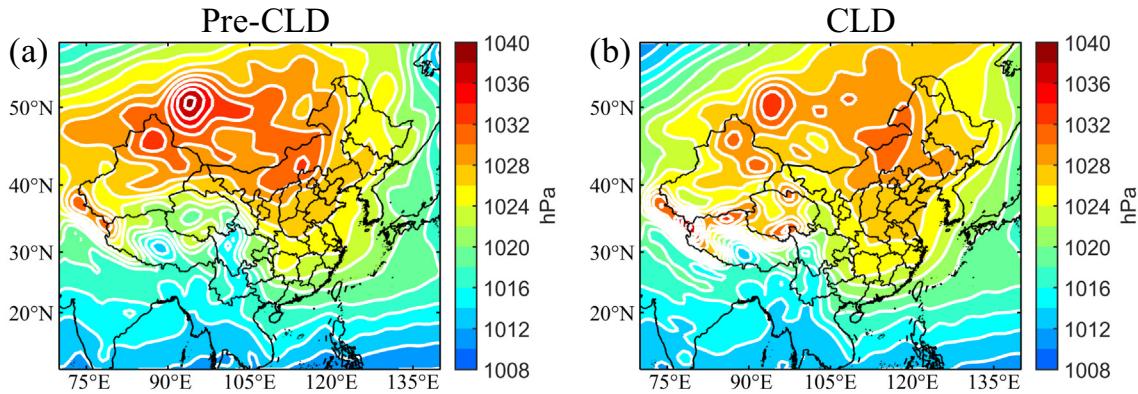

Fig. 5. Averaged sea-level pressure during the pre-CLD and CLD periods. Data are from the National Center for Environmental Prediction (NCEP) FNL Operational Model Global Tropospheric Analyses dataset.

77%, and 18% in NC, CC, and SC, respectively (Fig. 2f). These results reveal the diverse response of O_3 during the lockdown in different regions, especially for the daytime. The changes in the O_x ($NO_2 + O_3$) concentration (Fig. 3a), which takes into account the NO titration, also varied in different regions. The daytime average O_x levels increased by 4% in NC and by 11% in CC, and decreased by 29% in SC. These results suggest that the NO titration effect was not the only cause of the O_3 increase in northern and central China, as O_x would have decreased with sharply reduced NO_x emissions.

3.2. Contribution of meteorological changes and emission reductions to O_3

Ground-level O_3 is influenced by both chemical reactions of O_3 precursors and meteorology. In this study, we used the WRF-CMAQ model to separate the impacts of meteorological changes and emission reductions on the changes in O_3 across China (Fig. S2), which reveals significant contributions of both meteorology (over most of continental China) and emissions (mainly in populated areas of eastern China). Fig. 4 shows the more detailed results for the NC, CC, and SC regions for both daytime and nighttime and Fig. S3 presents the meteorological impact and emission impact in terms of percent change. The observed

O_3 changes in these regions were reasonably captured by the simulations. For the daytime average, the O_3 increase in NC was attributed to the comparable contributions from both meteorological changes (58%) and emission reductions (42%) (Fig. 4a). In CC (Fig. 4b), the meteorological change (98%) was the primary cause of the O_3 increase, whereas the contribution of emission reduction was much lower (2%). In SC (Fig. 4c), the meteorological changes (73%) and emission reductions (27%) both contributed to the O_3 decrease. During nighttime, the emission reduction increased O_3 in all three regions (including SC), and its impact was stronger; the effect of meteorological changes weakened at night (Fig. S3).

3.3. Impacts of meteorological changes on O_3

The impacts of meteorological changes on O_3 for the NC, CC, and SC regions can be explained by the changes in the weather pattern and specific meteorological factors. In winter, continental China is generally controlled by a cold high-pressure system (Fig. 5). During our study period, the center of this high-pressure system was located in northern China, moving southward from the pre-CLD to the CLD period, with weakening strength. The high-pressure system therefore became

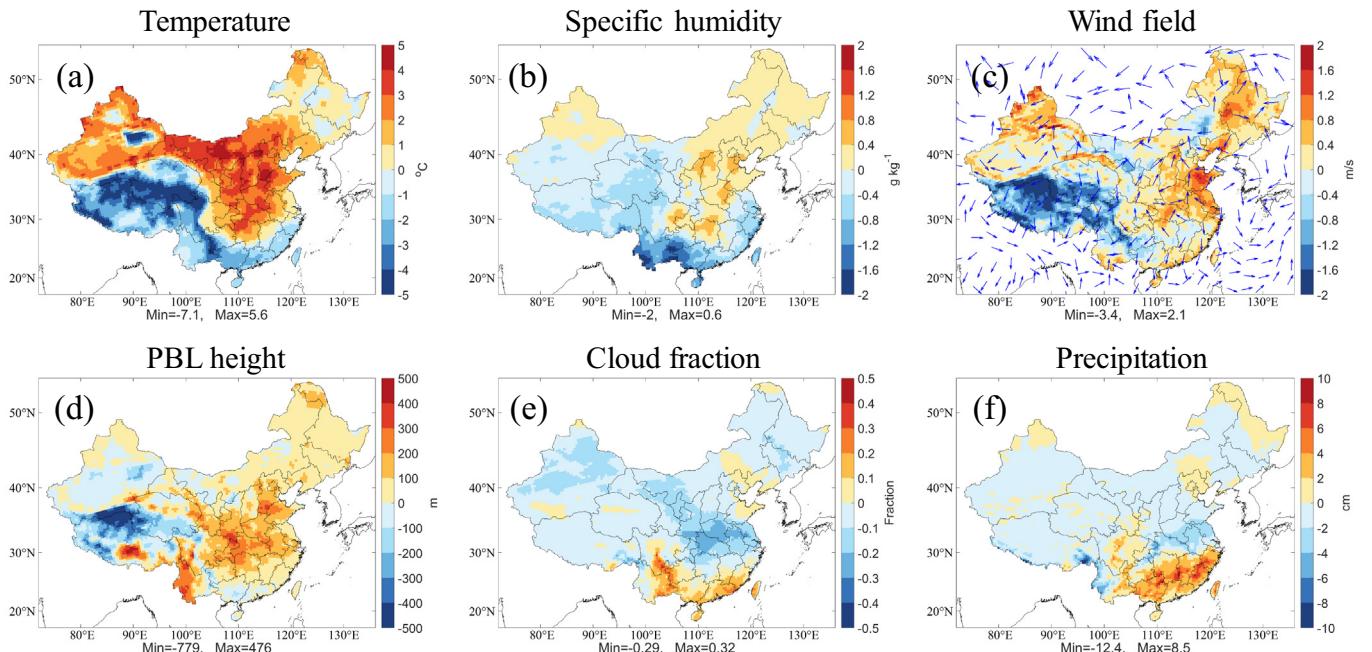

Fig. 6. Model simulated changes in daytime temperature at 2 m height, specific humidity at 2 m height, wind field at 10 m height, planetary boundary layer (PBL) height, cloud fraction, and precipitation during CLD period relative to pre-CLD period. In panel (c), the shaded color and vector represent the wind speed and wind direction, respectively.

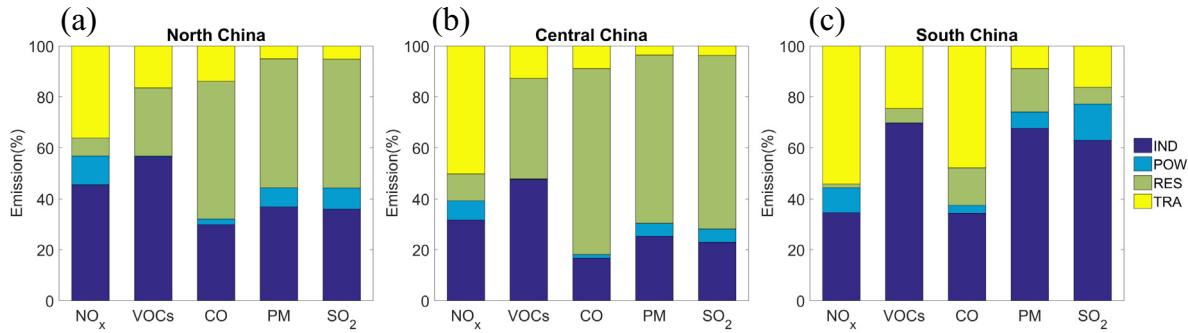

Fig. 7. Percentage contribution to NO_x, VOCs, CO, PM, and SO₂ emissions from industrial (IND), power plant (POW), residential (RES), and transportation (TRA) sectors in (a) north China, (b) central China, and (c) south China. Emission data are from 2017 MEIC (<http://meicmodel.org>) with estimated scaling factors from 2017 to 2020.

increasingly dominant in southern China, and the strengthened southward winds brought colder air masses from the north (Fig. 6c), which decreased the temperature locally (Fig. 6a). In contrast, in central and northern China, the winds shifted to a more northward direction,

transporting warmer air masses from the south (Fig. 6c), which increased the temperature (Fig. 6a). During daytime, the decrease (increase) in temperature in the SC region (CC and NC regions) weakened (enhanced) the surface O₃ chemical production. Biogenic emission is an important

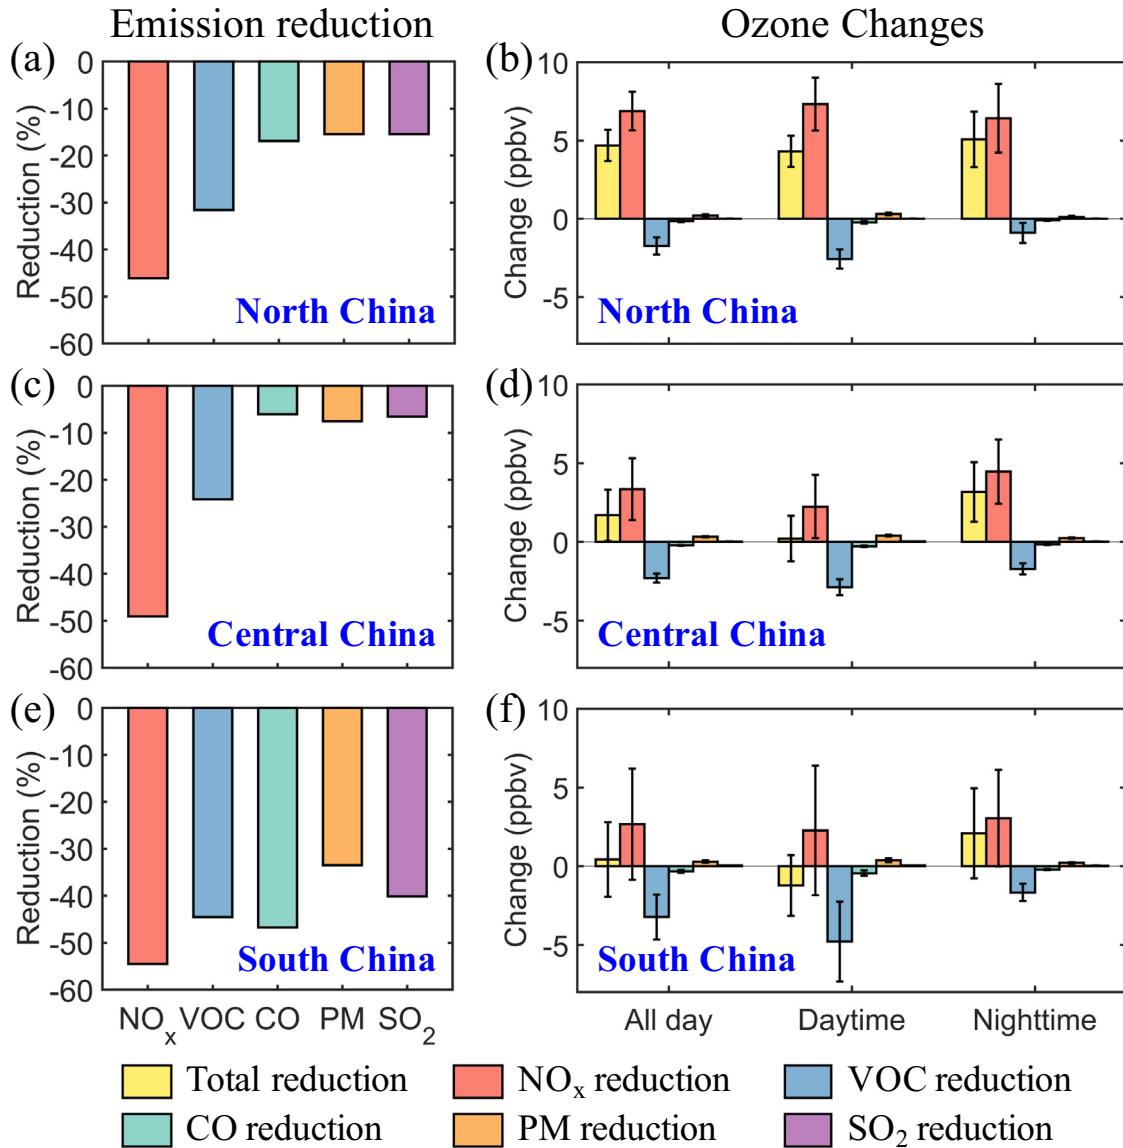

Fig. 8. The estimated reductions of multi-pollutant emissions due to the COVID-19 lockdown and their impacts on the O₃ changes for three regions. (a, c, e) The estimated reductions of NO_x, VOC, CO, PM, and SO₂ emissions during the CLD period compared with the pre-CLD period for north China, central China, and south China. (b, d, f) The impacts of different pollutant emission reductions due to the lockdown on O₃ changes for the three regions. The O₃ changes for all-day average, daytime average, and nighttime average are presented. The error bars are the standard deviations.

source of VOCs and thereby contributes to O₃ formation in China (Wu et al., 2020). The temperature changes led to an increase (decrease) of biogenic emissions in the CC (SC) region (Fig. S4). Thus, the temperature changes increased (decreased) O₃ in the CC (SC) region by influencing chemical reaction rates directly (Fu et al., 2015; Steiner et al., 2010) and altering biogenic emissions indirectly (Im et al., 2011; Liu and Wang, 2020a).

The changes in the weather pattern also resulted in less clouds and precipitation in northern and central China, but more clouds and precipitation in southern China (Fig. 6e and f). Clouds can reduce the amount of solar radiation reaching the surface and thus the chemical production of O₃ (Lelieveld and Crutzen, 1990), while precipitation can also reduce O₃ through the scavenging of its precursors (Seinfeld and Pandis, 2006; Shan et al., 2008). The cloud and precipitation patterns therefore contributed to O₃ increases in CC and NC and decreases in SC. Furthermore, in NC and CC, the significant increase in the planetary boundary layer height during the lockdown (Fig. 6d) might promote the transport of O₃ from the upper air to the surface, contributing to the O₃ increase in these regions (He et al., 2017; Sun et al., 2009). The increase (decrease) in specific humidity in NC and CC (SC) might also have contributed to the decrease (increase) in O₃ mixing ratios in those regions (Li et al., 2019c; Ma et al., 2019) (Fig. 6b). During nighttime, the changes in meteorological factors were similar to those in daytime (Fig. S5) but

exerted smaller impacts on O₃ changes due to the decreasing effects of temperature and cloud cover (negligible biogenic emissions and solar radiation).

3.4. Response of O₃ to emission reductions

We further investigated the impact of multi-pollutant reductions on the O₃ changes. Because transportation and industrial activities were reduced significantly during the lockdown and they are the major sources of NO_x (>80%) and VOCs (>60%) (Fig. 7), the estimated reductions of NO_x and VOC emissions were more significant than those for CO, particulate matter (PM), and SO₂ (Fig. 8a, c, e). The NO_x emission reductions were 46%, 49%, and 55% in the NC, CC, and SC regions, respectively, while the respective reductions for VOC emissions were 32%, 24%, and 45%. The relationship between O₃ and the emissions of its precursors is non-linear. We used the ratio of production rates between H₂O₂ and HNO₃ ($P_{H_2O_2}/P_{HNO_3}$) (Gaubert et al., 2021; Tonnesen and Dennis, 2000) to identify the O₃ formation regime in China for the periods before and during the lockdown (Fig. 9). $P_{H_2O_2}/P_{HNO_3} < 0.06$ is VOC-limited region; $P_{H_2O_2}/P_{HNO_3} \geq 0.2$ is NO_x-limited region, and $0.06 \leq P_{H_2O_2}/P_{HNO_3} < 0.2$ is the transition zone. For the pre-CLD period, during daytime, the VOC-limited (or NO_x-saturated) regions included North China Plain and other urban areas, while NO_x-limited regions located

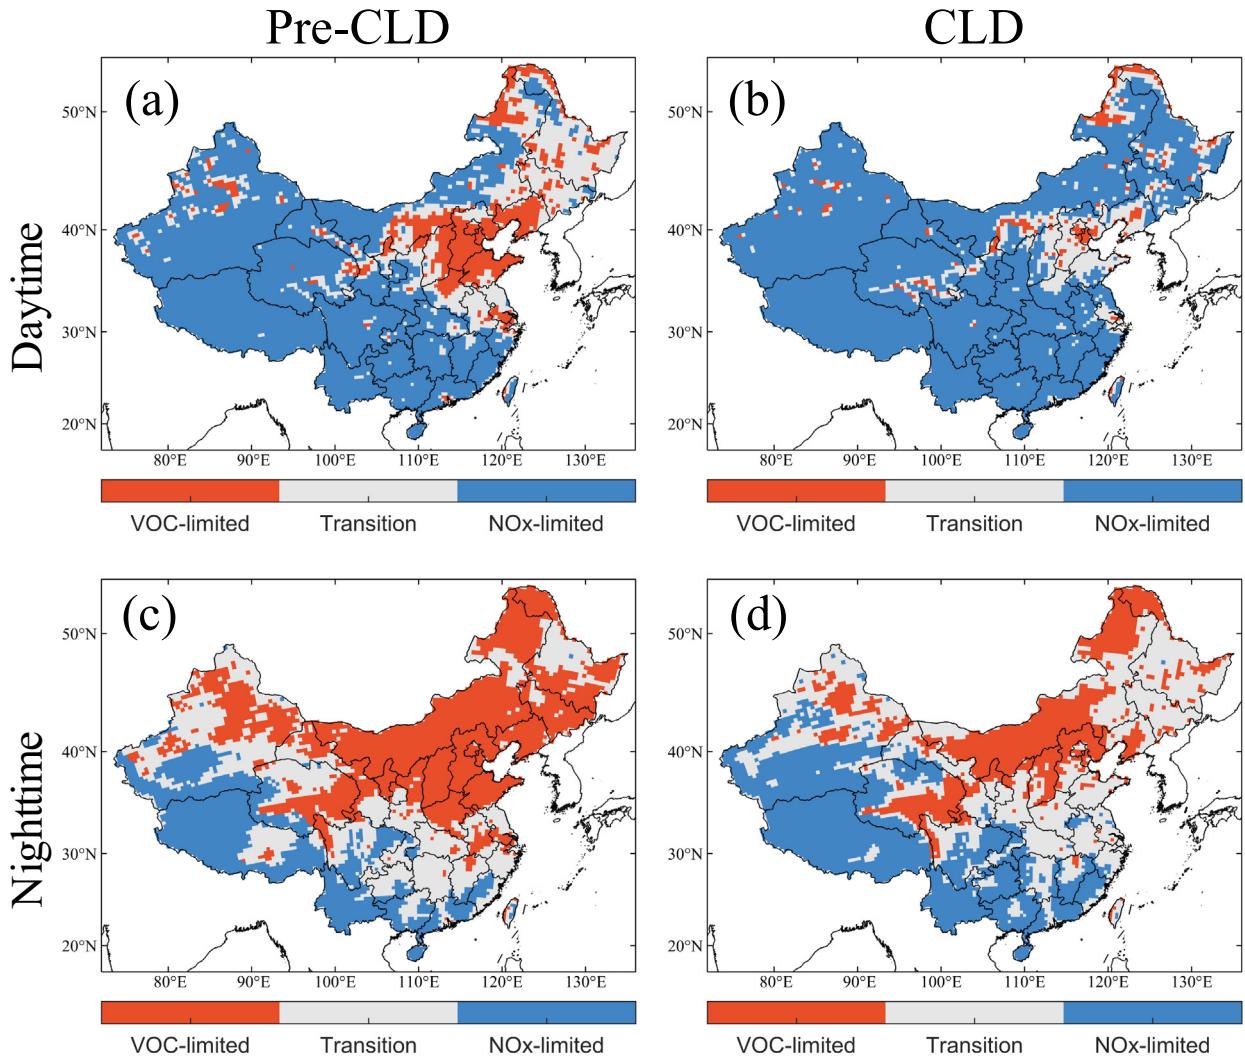

Fig. 9. Ozone formation regime in the daytime and nighttime before and during the lockdown periods estimated by the ratio of the production rates of hydrogen peroxide to nitric acid ($P_{H_2O_2}/P_{HNO_3}$). VOC-limited region: $P_{H_2O_2}/P_{HNO_3} < 0.06$; NO_x-limited region: $P_{H_2O_2}/P_{HNO_3} \geq 0.2$, Transition zone: $0.06 \leq P_{H_2O_2}/P_{HNO_3} < 0.2$. The production rates of H₂O₂ and HNO₃ were calculated by the integrated reaction rate (IRR) diagnose tool in the CMAQ model.

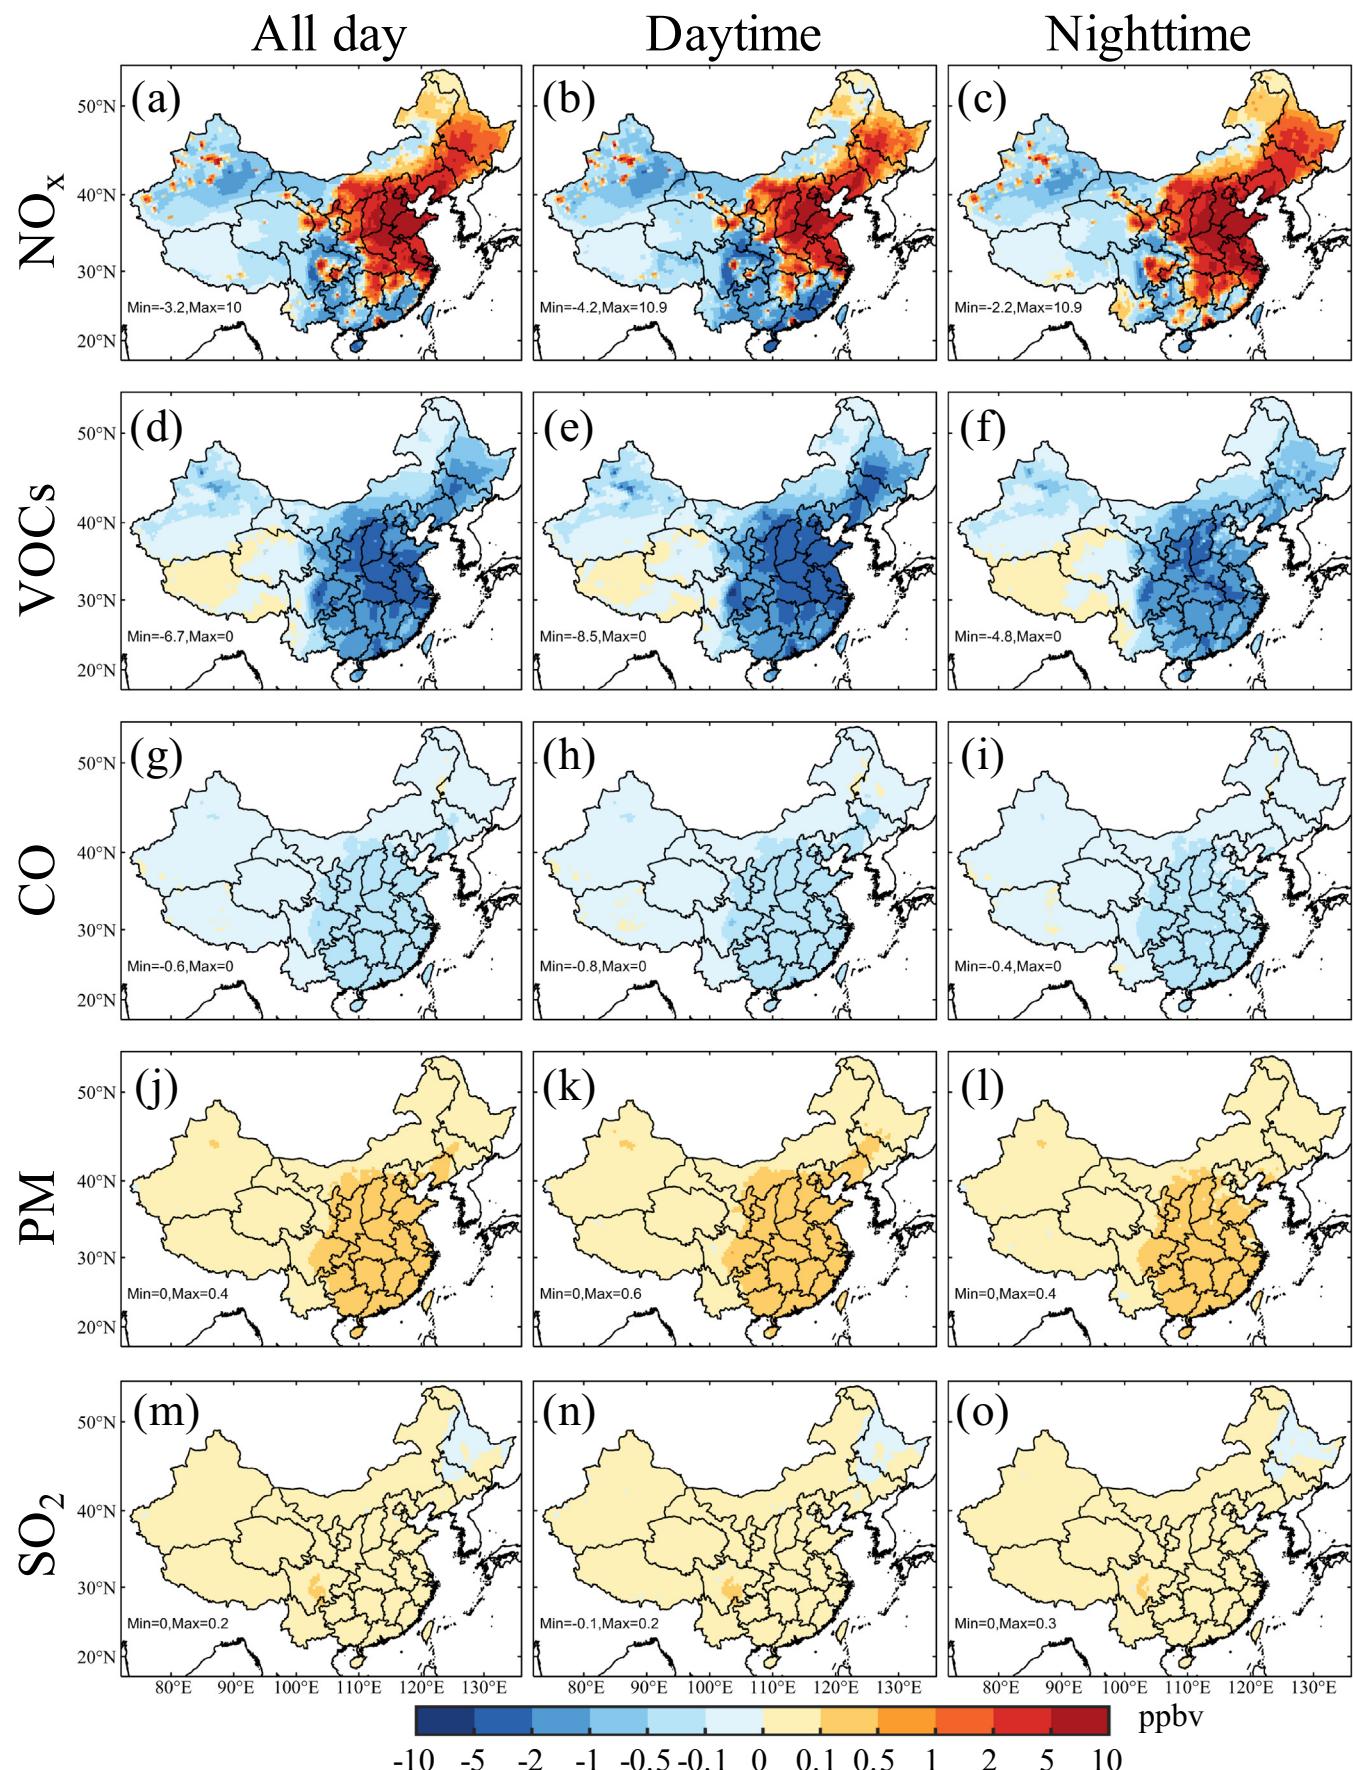

Fig. 10. Model simulated changes in O₃ mixing ratios for all-day average, daytime average, and nighttime average due to the reductions of NO_x, VOC, CO, PM, and SO₂ emissions during the CLD period compared with the pre-CLD period.

in southern China and other rural areas (Fig. 9a). During nighttime, most regions are VOC-limited (Fig. 9c).

The O₃ formation regime determines the response of O₃ to the NO_x reduction during the CLD period. During daytime, NO_x reduction increased O₃ in NO_x-saturated regions, but decreased it in NO_x-limited regions (Fig. 10b). We also found that although the daytime O₃ formation regime in most regions shifted from the VOC-limited regime to the NO_x-limited regime after the emission reductions during the CLD period, the daytime O₃ formation in the North China Plain was still controlled by the VOC level (Fig. 9b), which suggests that the NO_x level is still high in this region. During nighttime, the reduction of NO_x emission contributed increased O₃ due to the NO titration effect in large areas (Fig. 10c). The reduction of VOC emission decreased O₃ across China (Fig. 10d-f). As an O₃ precursor, the reduction of CO emission also contributed to a small decrease in the O₃ mixing ratio (Fig. 10g-i); in contrast, the PM and SO₂ emissions reductions increased O₃ (Fig. 10j-o) through the weakening of aerosol effects (Li et al., 2019a; Liu and Wang, 2020b), but their impacts were much smaller and were insignificant (< 1 ppbv) due to the smaller reductions, compared with NO_x and VOCs.

The response of O₃ to the emission reductions in different regions depended on the levels of NO_x and VOC reductions. For the daytime average, in the NO_x-saturated NC region, the O₃ increase by the NO_x reduction counteracted the O₃ decrease by the VOC emission reduction, leading to the decrease in increased O₃ production rates (Fig. 11) and a substantial net O₃ increase (Fig. 8b). In CC, the contributions of the NO_x and VOC reductions were comparable in magnitude, and their opposing impacts resulted in only a slight change in O₃ (Fig. 8d). In the NO_x-limited SC region, the impact of the NO_x reduction on O₃ was smaller than that of the reduction of VOCs, leading to the decrease in O₃ production rates (Fig. 11), and a net decrease in O₃ (Fig. 8f). During nighttime, the effect of the VOC reduction was weakened due to the lower rate of degradation of VOCs by radicals compared with daytime, and the O₃ level increased in all three regions due to decreases in the NO titration effect (Fig. 11). The impacts of emission reductions on whole-day average O₃ were similar to those during daytime.

The above modeling results show that the contribution of NO_x reductions (by 46%–55%) to the rise of O₃ decreased from NC to CC and to SC, reflecting the decreasing level of NO_x saturation from north to south. In contrast, the impact of the estimated VOC reduction on O₃ increased from north to south, which can in part be attributed to the regional variation of VOC reductions. In the SC region, transportation and industry are the predominant sources of VOCs (97%, compared with 85% and 60% in NC and CC, respectively) (Fig. 7). During the CLD period, the reduction of VOC emission in SC (45%) was significant and comparable with the NO_x reduction (55%). In contrast, the VOC reductions in the NC (32%) and CC (24%) regions were much lower (Fig. 8a, c) and could not offset the impact of NO_x reduction on O₃. The residential sector (mainly household coal burning) is an important source of VOC emission in the NC and CC regions, whereas its contribution is smaller in SC. The residential emissions increased during the CLD period because many migrant workers came back for the Chinese New Year holiday and were stranded there due to the lockdown (Wang et al., 2020a; Wang et al., 2020b).

4. Conclusion

The first country-wide lockdown during the COVID-19 outbreak in China drastically reduced transportation and industrial activities, leading to sharp declines in air pollutant emissions from these sectors. Surface O₃ in urban areas of China responded differently in the northern (increase) and southern regions (decrease) compared to the three-week period before the lockdown, which can be explained by changes in meteorology and differences in the O₃ chemistry regimes and the magnitudes of precursor reductions in these regions. The model simulated contributions of meteorology to daytime O₃ changes were larger or comparable to most regions. The extent of VOC reduction, which suppressed O₃ formation, was insufficient to offset the large NO titration effect during daytime in northern China, and that larger reductions of VOCs (e.g., from residential sectors) would have been needed to reduce the O₃ concentration in the northern and central China. The rising O₃ concentration in northern China during the COVID-19 lockdown and

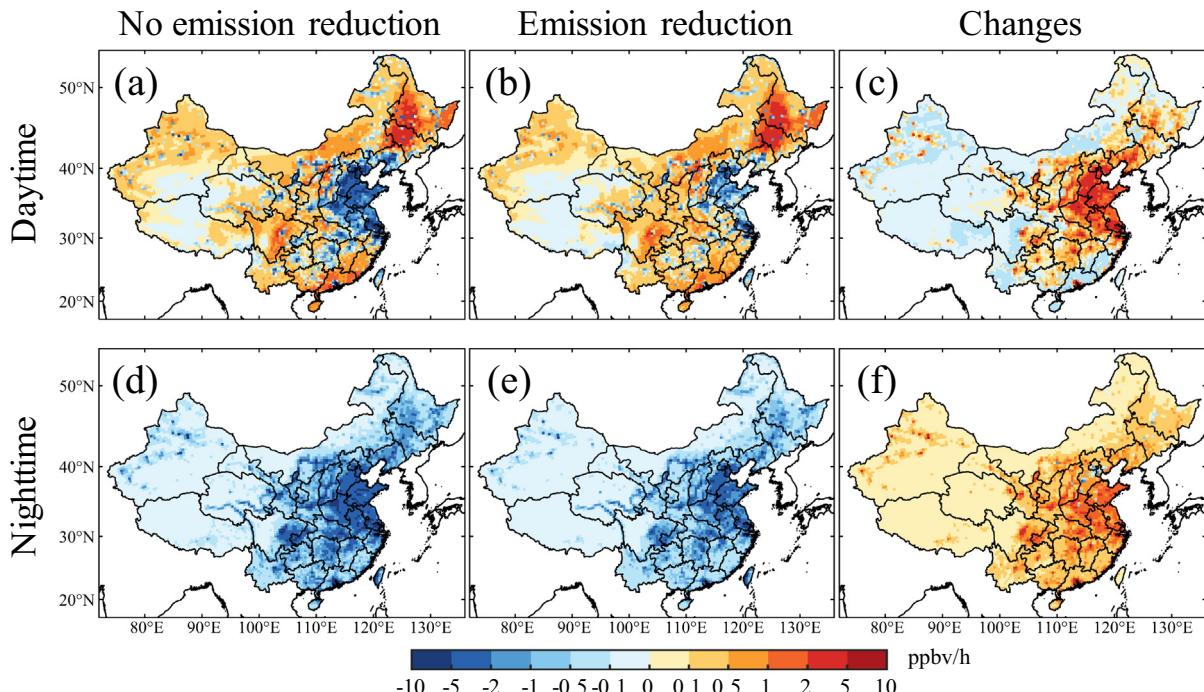

Fig. 11. O₃ chemical production rates before and after the anthropogenic emission reductions and the changes during the COVID-19 lockdown period. The chemical production rates were calculated by the process analysis method in the CMAQ model.

in recent winters should receive greater attention because O₃ boosts the atmospheric oxidative capacity and therefore production of secondary aerosols (Fu et al., 2020; Huang et al., 2021; Zhu et al., 2020), which are important components of winter haze in northern China. Our findings in China are relevant to untangling the underlying factors driving the O₃ changes in other parts of the world during their COVID-19 lockdowns.

Acknowledgements

This work was supported by the Hong Kong Research Grants Council (T24-504/17-N and A-PolyU502/16) and the National Natural Science Foundation of China (91844301). B.G. acknowledges support by the National Center for Atmospheric Research, which is a major facility sponsored by the National Science Foundation under cooperative agreement no. 1852977. We would like to thank Prof. Qiang Zhang from Tsinghua University for providing the emission inventory.

Appendix A. Supplementary data

Supplementary data to this article can be found online at <https://doi.org/10.1016/j.scitotenv.2021.147739>.
